

Excited charmonium spectrum from anisotropic lattices

X. Liao and T. Manke

Physics Department, Columbia University, New York, NY 10027, USA

Abstract

We present our final results for the excited charmonium spectrum from a quenched calculation using a fully relativistic anisotropic lattice QCD action. A detailed excited charmonium spectrum is obtained, including both the exotic hybrids (with $J^{PC} = 1^{-+}, 0^{+-}, 2^{+-}$) and orbitally excited mesons (with orbital angular momentum up to 3). Using three different lattice spacings (0.197, 0.131, and 0.092 fm), we perform a continuum extrapolation of the spectrum. We convert our results in lattice units to physical values using lattice scales set by the $^1P_1 - 1S$ splitting. The lowest lying exotic hybrid 1^{-+} lies at 4.428(41) GeV, slightly above the $D^{**}D$ (S+P wave) threshold of 4.287 GeV. Another two exotic hybrids 0^{+-} and 2^{+-} are determined to be 4.70(17) GeV and 4.895(88) GeV, respectively. Our finite volume analysis confirms that our lattices are large enough to accommodate all the excited states reported here.

I. INTRODUCTION

The hadron spectrum is one of the most prominent non-perturbative consequences of QCD. Over the past two decades, enormous progress has been achieved in developing the non-perturbative techniques needed to predict these hadron masses from first principles. It is crucial that our theoretical techniques reproduce the observed hadron spectrum to justify predictions for more complicated quantities such as the weak matrix elements.

On the experimental front, data for the excited charmonium spectrum above the $D\bar{D}$ threshold are scarce, and no heavy hybrid signal has been observed yet, even though some potential candidates for light exotic hybrids have been found and discussed extensively [1]. However, the situation will change dramatically in the next few years with more data from the B -factories PEP-II (Babar) and KEKB (Belle). Even more important results are promised by the focused charm physics programs proposed for the upgraded CLEO-c detector [2] (expected to start running in early 2003) and the new BESIII detector [3] (expected in 2005-2006) at BEPC (Beijing Electron-Position Collider). Both CLEO-c and BESIII will collect large amounts of data for the charmonium spectrum above the $D\bar{D}$ threshold and provide badly needed, accurate results for the excited charmonium spectrum, including radially and orbitally excited conventional $c\bar{c}$ mesons and gluon-rich states (glueballs and

hybrids). Better theoretical predictions, especially those from lattice QCD calculations, will provide important guidance for these experimental efforts.

In contrast to the light hadron spectrum, the heavy quark spectrum is much better understood theoretically with various phenomenological models such as the static potential models and, more reliably, with the low energy effective theories such as non-relativistic QCD (NRQCD) [4,5]. NRQCD has been the dominant approach to the study of heavy quark physics for many years and has been quite successful, especially for the bottomonium systems. However, it is rather difficult to control the systematic errors of NRQCD, including the relativistic corrections and the radiative corrections, which were shown to be quite large for charmonium [6,7], and still sizable for bottomonium [8,9]. Of even greater concern are the finite lattice spacing artifacts that could not be controlled by taking the continuum limit because of the restriction: $M_q a > 1$. Nonetheless, all these approximations to QCD provide important guidance and calibration for fully relativistic lattice QCD calculations and are quite useful for the understanding of systematic errors such as those arising from quenching and finite volume effects.

Our ultimate goal is to determine the heavy quark spectrum (extrapolated to the continuum limit) from fully relativistic lattice QCD. However, the large separation of energy scales ($m_q v^2 \ll m_q v \ll m_q$) in the heavy quark system makes it prohibitively expensive to study heavy quarks on a conventional isotropic lattice. Earlier relativistic studies employed the “Fermilab approach” [10,11], which uses a space-time asymmetric, $\mathcal{O}(a)$ improved action to control the $\mathcal{O}(M_q a)$ errors on an isotropic lattice with equal lattice spacings in the space and time direction ($a_t = a_s$). In this study, we employ a newer approach called relativistic anisotropic lattice QCD, which is a generalization of the “Fermilab action” to an anisotropic lattice with $a_t < a_s$. The anisotropic lattice gauge action was developed in the 1980s [12], and has been used quite successfully for glueball spectrum calculations [13,14] and thermodynamic studies [15]. However, it was not until the late 1990s that an improved relativistic anisotropic fermion action was implemented for Wilson-type quarks [16,17]. Since then, the relativistic anisotropic lattice technique has been applied to calculate the heavy quark spectrum with unprecedented accuracy, including both charmonium [17–19] and bottomonium states [20].

In addition to conventional mesons made of a quark-antiquark pair (within the naive quark model), hybrid mesons containing valence gluons are also believed to be present in the nature¹. Phenomenological studies using the Born-Oppenheimer approximation [21], the bag model [22,23], the flux-tube model [24], and the QCD sum rules [25,26], have provided the theoretical evidence and given semi-quantitative estimates for these hybrid states, which are further confirmed by NRQCD [27] and standard lattice QCD calculations [28]. In the naive quark model, not all J^{PC} quantum numbers are available, since the parity (P) and charge conjugation (C) of a conventional $q\bar{q}$ meson are given by:

$$P = (-1)^{L+1}, C = (-1)^{L+S}, \quad (1.1)$$

where L and S are the orbital angular momentum and spin of the $q\bar{q}$ pair. Hybrid states

¹We use $q\bar{q}$ to represent a conventional meson (a pure quarkonium) and $q\bar{q}g$ for a hybrid meson.

possessing so-called exotic quantum numbers (eg. 1^{-+} , 0^{+-} , and 2^{+-}) have attracted considerable attention because such states do not mix with the conventional $q\bar{q}$ mesons and therefore should be more easily distinguished in experiments than can non-exotic hybrids. More comprehensive reviews of hybrid excitations can be found in Ref. [1,29].

However, like all the other highly excited states, these hybrid mesons are difficult to measure accurately on a lattice because their signals are much noisier than those of the low lying mesons. Thus, it is crucial to have fine temporal resolution as well as highly optimized operators to collect as much information as possible from meson correlation functions even at short time separation. The anisotropic lattice technique provides an efficient framework for such high precision calculations, because it allows independent control of the temporal and spacial lattice spacings, thereby permitting simulations with a very fine grid in the temporal direction.

In this work, we employ well optimized extended operators to study the excited charmonium spectrum, including the orbitally excited mesons (P-, D-, and F-wave) and hybrid mesons with exotic quantum numbers. This complements our group's previous charmonium calculations on anisotropic lattices [18], which used only local operators and focused on the conventional low lying S-wave and P-wave $c\bar{c}$ mesons. This paper is a follow-up and complete analysis of our earlier work [30].

This paper is organized as follows. Sec. II describes the anisotropic lattice gauge action and fermion action. A discussion of the construction and optimization of meson operators is given in section III. Sec. IV contains the details of our simulations, including simulation parameters and some measures taken to improve computational efficiency. In section V, we present our spectrum results and discuss the systematic errors and the theoretical and experimental implications. Section VI contains concluding remarks. In the appendix, we describe the notation used in this paper, our meson naming convention, and some relevant properties of the hyper-cubic symmetry group.

II. ANISOTROPIC LATTICE ACTION

We employ an anisotropic gluon action [12], which is accurate up to $\mathcal{O}(a_s^2, a_t^2)$ discretization errors:

$$S = -\beta \left(\xi_0^{-1} \sum_{x,i>j} P_{ij}(x) + \xi_0 \sum_{x,i} P_{i0}(x) \right) . \quad (2.1)$$

This is the standard Wilson action written in terms of simple plaquettes, $P_{\mu\nu}(x)$. Here 0 labels the time component and the index $i = 1, 2, 3$ runs over the three spatial directions. The parameters β and ξ_0 are the bare coupling and bare anisotropy respectively, which determine the spatial lattice spacing, a_s , and the renormalized anisotropy, ξ , of the quenched lattice. The continuum limit should be taken at fixed anisotropy, $\xi = a_s/a_t$. For the heavy quark propagation in the gluon background we used the ‘‘anisotropic clover’’ formulation as first described in [17]. The discretized form of the continuum Dirac operator, $Q = m_q + \not{D}$, reads

$$Q = m_0 + \nu_s W_i \gamma_i + \nu_t W_0 \gamma_0 - \frac{a_s}{2} [c_t \sigma_{0k} F_{0k} + c_s \sigma_{kl} F_{kl}] , \\ W_\mu = \nabla_\mu - (a_\mu/2) \gamma_\mu \Delta_\mu . \quad (2.2)$$

Here ∇_μ is the symmetric lattice derivative:

$$\bar{q}(x) a_\mu \nabla_\mu q(x) = \bar{q}(x) U_\mu(x) q(x + \mu) - \bar{q}(x) U_{-\mu}(x) q(x - \mu). \quad (2.3)$$

and Δ_μ is defined by $a_\mu^2 \Delta_\mu q(x) \equiv U_\mu(x) q(x + \mu) - 2 q(x) + U_{-\mu}(x) q(x - \mu)$. For the field tensor $F_{\mu\nu}$ we choose the traceless cloverleaf definition which sums the 4 plaquettes centered at point x in the (μ, ν) plane:

$$a_\mu a_\nu F_{\mu\nu}(x) \equiv \frac{i}{2} [P_{\mu\nu}(x) + P_{\nu\bar{\mu}}(x) + P_{\bar{\mu}\bar{\nu}}(x) + P_{\bar{\nu}\mu}(x) - h.c.] \quad , \quad (2.4)$$

where $\bar{\mu}$ indicates the negative direction $-\hat{\mu}$, so $P_{\bar{\mu}\bar{\nu}}(x)$ represents $U^\dagger(x - \hat{\mu}, \mu) U^\dagger(x - \hat{\mu} - \hat{\nu}, \nu) U(x - \hat{\mu} - \hat{\nu}, \mu) U(x - \hat{\nu}, \nu)$. This is indeed the most general anisotropic quark action including all operators to dimension 5 up to $O(3)$ symmetric field redefinition. We have chosen Wilson's combination, W_μ , of first and second derivative terms so as to both remove all doublers and ensure the full projection property. The five parameters in Eq. (2.2) are all related to the quark mass, m_q , and the gauge coupling as they appear in the continuum action. By tuning them appropriately we can remove all $\mathcal{O}(a)$ errors and re-establish space-time axis-interchange symmetry for long-distance physics. A more detailed discussion of these parameters can be found in Refs [17,18,20,31].

Classical values for these parameters have been given in Ref. [18]:

$$m_0 = m_q \left(1 + \frac{1}{2} a_s m_q\right) \quad (2.5)$$

$$\nu_t = \nu_s \frac{1 + \frac{1}{2} a_s m_q}{1 + \frac{1}{2} a_t m_q} \quad (2.6)$$

$$c_s = \nu_s \quad (2.7)$$

$$c_t = \frac{1}{2} \left(\nu_s + \nu_t \frac{a_t}{a_s} \right) \quad . \quad (2.8)$$

Simple field rescaling enables us to set one of the above coefficients at will. For convenience we fix $\nu_s = 1$ and adjust ν_t non-perturbatively requiring that the mesons obey a relativistic dispersion relation ($c(\mathbf{0}) = 1$):

$$E^2(\mathbf{p}) = E^2(\mathbf{0}) + c^2(\mathbf{p}) \mathbf{p}^2 + \mathcal{O}(\mathbf{p}^4) \dots \quad (2.9)$$

We also choose m_0 non-perturbatively, such that the spin average of the lowest S-wave mesons ($1S$) matches its experimental value: $\frac{3}{4}M(^3S_1) + \frac{1}{4}M(^1S_0) = 3.067$ GeV for charmonium. For the clover coefficients (c_s, c_t) we take their classical estimates from Eqs. (2.7) and (2.8) and augment them by tadpole improvement.

$$c_s \rightarrow c_s / (u_s^3) \quad (2.10)$$

$$c_t \rightarrow c_t / (u_t u_s^2) \quad (2.11)$$

The tadpole coefficients have been determined from the average link in Landau gauge: $u_\mu = 1/3 \langle \text{tr } U_\mu(x) \rangle_{\text{Landau}}$. For brevity we will refer to this as the *Landau* scheme. Any other

choice for (c_s, c_t) will have the same continuum limit, but with this prescription we expect only small $\mathcal{O}(\alpha_s a)$ discretization errors.

Our action is a generalization of the ‘‘Fermilab action’’ [10], which can be considered as a special case of our action with $\xi = 1$. It has been demonstrated [17] that the mass dependence of the input parameters is much smaller for an anisotropic lattice ($\xi > 1$), which makes the tuning of the parameters easier in the anisotropic case.

III. MESON MASS MEASUREMENT

We extract meson masses from the time dependence of Euclidean-space two-point correlation functions, which is the standard procedure to determine hadron masses from lattice calculations. For the hadron source and sink, we use both local and extended meson operators constructed from fundamental bilinears in the form of

$$M(x) = \bar{\Psi}(x) \Gamma_i \nabla_j[U] \nabla_k[U] \Psi(x) \quad , \quad (3.1)$$

here Γ_i is one of the 16 Dirac Γ -matrices and ∇_j is the symmetric spatial lattice derivative operator (see Eq. 2.3). To obtain the dispersion relation, $E(\mathbf{p})$, we project the meson correlator onto several different non-zero momenta by inserting the appropriate phase factors, $\exp(-i\mathbf{p}\mathbf{x})$, at the sink, and sum the sink over a spatial hyper-plane:

$$M(t, \mathbf{p}) = \sum_{\mathbf{x}} M(t, \mathbf{x}) \exp(-i\mathbf{p}\mathbf{x}), \quad (3.2)$$

where

$$\mathbf{p} = \left(\frac{2\pi}{N_s} \right) \mathbf{n} \quad \text{with} \quad \mathbf{n} = (0, 0, 0), (1, 0, 0), (1, 1, 0), (2, 0, 0), (2, 2, 0), \dots \quad (3.3)$$

To vary the overlap of a meson operator with the ground state and excited states, we also implement a combination of various iterative smearing prescriptions for the quark fields and gauge links, which is described below.

For the quark fields, we use box sources to approximate the spatial distribution of the quark field. More specifically, we set the source to be unity within a spatial hyper-cube and zero elsewhere. This allows us to vary the extent in a rather straight forward manner. As such a formulation is not gauge invariant, we have to fix the gauge, and we choose the Coloumb gauge for convenience. Alternatively, we can use a gauge invariant formulation, where repeated action of the gauge invariant Laplacian generates a Gaussian-like distribution and provides finer control of the overlap with different states:

$$\Psi(x) \rightarrow \Psi^{(n)}(x) = \left(1 - \frac{\epsilon}{n} \nabla^2[U] \right)^n \Psi(x) \quad (3.4)$$

This scheme is referred to as Jacobi smearing.

For the gauge field, we apply the well established iterative APE-style link fuzzing algorithm [32]:

$$\begin{aligned}
X_\mu(x) &= U_\mu(x) + \alpha * \sum_{\text{staples}} S(x, \mu) \\
U'_\mu(x) &= \mathcal{P}_{SU(3)} X_\mu(x) ,
\end{aligned} \tag{3.5}$$

where α is the link fuzzing parameter, $S(x, \mu)$ is one of the six staples around the link $U_\mu(x)$, and $\mathcal{P}_{SU(3)}$ is a projection back to $SU(3)$ by requiring the new link $U'_\mu(x)$ maximize:

$$\text{Re Tr} \left(U'_\mu(x) X_\mu(x) \right) . \tag{3.6}$$

The maximization is achieved by several Cabibbo-Marinari pseudo-heatbath update steps (fuzzing CM hits). We repeat the fuzzing step defined by Eq. 3.5 for N times (N is the fuzzing level). Link fuzzing is quite effective in suppressing gluon excitations and has been widely used in studies of glueball and hybrid hadrons.

This setup allows us to extract reliably both the ground state energies and their excitations from correlated multi-state fits to several smeared correlators, $C^s(t)$, with the same J^{PC} :

$$C^s(t, \mathbf{p}) \equiv \langle M(t, \mathbf{p}) M^s(0, \mathbf{p}) \rangle = \sum_{i=1}^{n_{\text{fit}}} a_i^s(\mathbf{p}) \left(e^{-E_i(\mathbf{p}) t} + e^{-E_i(\mathbf{p})(N_t-t)} \right) . \tag{3.7}$$

Since we are working in a relativistic setting, the second term takes into account the backward propagating piece from the temporal boundary.

We construct meson operators that have definite lattice quantum number R^{PC} , in which R is one of the five irreducible representations of the hyper-cubic group: A_1 , A_2 , E , T_1 , and T_2 . A brief discussion of the hyper-cubic group is given in appendix C, including our choice of bases that carry the irreducible representations and some relevant Clebsch-Gordan coefficients. However, determining the continuum quantum number J^{PC} of an operator is complicated by the fact that the mapping from the finite number of irreducible representations of hyper-cubic group to the infinite number of irreducible representations of the continuous rotation group is non-unique. Eq. 3.8 summarizes the mapping from R to the first few J numbers (up to 4).

$$\begin{aligned}
A_1 &\rightarrow J = 0, 4 \\
A_2 &\rightarrow J = 3 \\
T_1 &\rightarrow J = 1, 3, 4 \\
T_2 &\rightarrow J = 2, 3, 4 \\
E &\rightarrow J = 2, 4
\end{aligned} \tag{3.8}$$

In most cases, we are only interested in the lowest lying state, which can be extracted from a one-state fit at large time separation or from a multi-state fit at shorter time separation. However, the lowest state does not always correspond to the lowest J number, the nature of a state (orbital excitation, radial excitation, gluonic excitation, and etc.) must also be taken into account. A notable example is meson operator $b_1 \times D_T T_2$ (detailed in Table VII), which projects to both $J = 2$ and $J = 3$ according to table 3.8. The first guess is that the ground state has $J = 2$ and is degenerate with the ground state of operator $b_1 \times D_T E$. However, 2^{+-} is an exotic hybrid meson, which is much heavier than the non-exotic 3^{+-} state. Therefore,

the ground state of $b_1 \times D_{T_2}$ should have quantum number $J = 3$ and be degenerate with $b_1 \times D_{A_2}$, which is confirmed by our calculation. Table VII summarizes all the meson operators used in this work and the quantum numbers (both lattice and continuum) of the ground states. Our naming convention is explained in appendix B 2.

Measuring meson correlators using extended operators is much more expensive than those using local operators, because more quark propagators are needed. We take some steps to improve the computational efficiency, which are explained in detail in section IV.

IV. SIMULATION DETAILS

The strategy and first results for charmonium have already been presented in [17,18]. The basic idea is to control large lattice spacing artifacts from the heavy quark mass by adjusting the temporal lattice spacing, a_t , so that $m_q a_t < 1$. We use $\xi = 2$ lattices with $\beta = 5.7, 5.9$, and 6.1 . Table I summarizes the parameters of our simulations.

For the generation of quenched gauge field configurations we employ a standard heat-bath algorithm as it is also used for isotropic lattices. The only necessary modification for simulating an anisotropic plaquette action is to rescale all temporal links with the bare anisotropy, ξ_0 . Depending on the gauge coupling and lattice size, we measure hadron propagators every 100-400 sweeps in the update process, which is sufficiently long for the lattices to decorrelate.

The renormalized anisotropy is related to the bare parameters through:

$$\xi = \eta(\xi, \beta) \xi_0. \quad (4.1)$$

A convenient parametrization for η is given in Ref. [17]

$$\eta(\xi, \beta) = 1 + \left(1 - \frac{1}{\xi}\right) \hat{\eta}_1(\xi) \frac{1 - 0.55055 \frac{g^2}{g^2}}{1 - 0.77810 \frac{g^2}{g^2}} \frac{g^2}{6}, \quad (4.2)$$

where $\hat{\eta}_1(\xi)$ is also determined non-perturbatively in Ref. [17] and $\eta(\xi, \infty) = 1$ as it ought to be. We use this form to determine the appropriate ξ_0 for each value of $\beta = 6/g^2 = 5.7, 5.9$, and 6.1 for $\xi = 2$.

Although the fine temporal resolution of an anisotropic lattice increases the number of measurements at short time separations, optimization of the meson operators is also quite important. The correlation between measurements of correlation function at different time slices reduces the amount of “useful” information for a correlated fit (in the case of strong correlation between neighboring time slices, little can be gained by using a higher anisotropy). Using multiple operators (with different optimization parameters) and applying multi-state fits can provide stronger constraints for the fits. A source of added difficulty is the possibility that the short distance correlators may be dominated by excited state signals, which can generate a false plateau, causing incorrect identification of an excited state as the ground state. We observe that the hybrid states are rather insensitive to the box size or quark field smearing, but are highly sensitive to gauge link fuzzing. Appropriate link fuzzing suppresses excited states because fuzzing reduces short-distance fluctuations of the gauge field background. This should be particularly important for hybrid states which are expected

to have a non-trivially excited gluonic component. We use multiple link fuzzing with the same quark smearing for hybrid states. In some cases, we employ fuzzing at the sink only to save computational time, tests are done to ensure good coupling to ground states.

Appendix B 1 describe in detail the calculation of meson correlators. First of all, we can reduce the number of quark propagators by reusing several basic quark propagators, since all the lattice derivative operators we use are linear combinations of basic derivative operators: unit(I), first derivative($\nabla_i(i = x, y, z)$), symmetric second derivative ($D_i = s_{ijk}\nabla_j\nabla_k$), asymmetric second derivative($B_i = \epsilon_{ijk}\nabla_j\nabla_k$), and symmetric diagonal second derivative $D_i^{diag} = \nabla_i\nabla_i$. It can be shown that we can construct all the meson correlation functions using these basic quark propagators. Furthermore, we can use a linear combination of these basic derivative operators to create a “white noise” source, which creates more than one quantum number, and rely on the sink operator to project to the quantum number of interest. Of course, using such “white noise” source saves computation time at the expense of an increased noise level. We carefully tested various combinations and chose those combinations that provide the best computational efficiency.

V. RESULTS AND DISCUSSIONS

We present our charmonium spectrum in Figure 1. A clear ordering of meson states according to orbital angular momentum and gluonic excitation is shown in Fig. 1, as well as the much smaller spin splittings. The low lying S-wave and P-wave mesons lie below the $D\bar{D}$ threshold, while the D-wave and F-wave mesons are above the $D\bar{D}$ threshold. Even higher hybrid excitations (with exotic quantum numbers $J^{PC} = 1^{-+}, 0^{+-}, 2^{+-}$) are found above the $D^{**}D$ threshold. A portion of the spectrum (the low lying 1S_0 , 3S_1 , and 1P_1) is taken from Columbia group’s previous work (Ref. [18]).

The lattice scale is set by the $^1P_1 - 1S$ splitting². Alternatively, we can use the Sommer scale r_0 [33], which was employed in Ref. [18]. Lattice scales from both methods (listed in Table I) agree well (within 2-4%) for charmonium, which, perhaps is not too suprising since r_0 is fixed from a potential model whose parameters were chosen specifically to reproduce the experimental charmonium spectrum. However, the discrepancy is rather large for bottomonium. We choose the $^1P_1 - 1S$ scale for this study to be consistent with previous NRQCD calculations.

A. Extrapolation to the continuum limit

The continuum limit has to be taken to remove the lattice discretization errors. This is also a major advantage of relativistic over non-relativistic QCD approach.

²We use 1P_1 instead of the spin averaged P-wave meson mass $1P = 1/9(^3P_0 + 3^3P_1 + 5^3P_2)$ because 3P_2 requires non-local operator which is much noisier and 1P_1 is extremely close to $1P$ ($^1P_1 - 1P = 0.86 \text{ MeV} \ll 1P - 1S$)

The continuum extrapolation of higher excitations is carried out as follows. We first calculate the dimensionless ratio of splittings between an excited state and the $1S$ state (the spin-averaged mass of S-wave mesons): $R(a_s) = (M - M(1S))/(M(^1P_1) - M(1S))$ for each lattice spacing a_s , and then extrapolate the ratio $R(a_s)$ to the continuum limit $a_s = 0$. In the end, the continuum result of the excited state is obtained by:

$$M|_{a_s=0} = R|_{a_s=0} * (^1P_1 - 1S)_{exp} + M(1S)_{exp} \quad (5.1)$$

where $(^1P_1 - 1S)_{exp} = 458.2$ MeV and $M(1S)_{exp} = 3067$ MeV are experimental values. Because the splitting between an excited state and the $1S$ state is rather insensitive to the $1S$ mass (or the quark mass), the imperfect tuning of $1S$ to its experimental value has negligible effect on the physical values obtained from Equation 5.1. However, the incorrect running of the coupling in a quenched simulation will still cause a mismatch of scales perceived by excited states and by the $^1P_1 - 1S$ splitting. In contrast, the fine structure splittings are very sensitive to the quark mass, so the deviation of the $1S$ mass from its experimental value should be taken into consideration when quoting the physical values for the spin splittings.

Using tadpole improved coefficients, we are able to remove the leading $\mathcal{O}(a_s)$ errors, which has been shown by previous studies [17,18,34]. Therefore, we extrapolate to the continuum limit assuming that the leading lattice spacing error is $\mathcal{O}(a_s^2)$.

B. Spin splittings

We first discuss our results for the spin splittings to demonstrate the necessity of a fully relativistic treatment, which is crucial for studying the fine structure of charmonium.

The Columbia group has studied in detail this spin splittings [18], but the 3P_2 state was missing because only local operators were used. Here, we measure all three P-wave triplet states 3P_J ($J = 0, 1, 2$) and calculate the P-wave triplet splitting ratio $R_{fs} = (^3P_2 - ^3P_1)/(^3P_1 - ^3P_0)$, which is highly sensitive to relativistic corrections but less affected by the systematic errors originating from fixing the overall scale in a quenched calculation. It has been shown that the velocity (v/c) expansion of NRQCD converges poorly for charmonium spin splittings [6,7]. Our R_{fs} results are given in table III. The result at $\beta = 6.1$ has a large error because the plateau of the fit sets in at a rather large temporal separation. Our result for the P-wave triplet splitting ratio R_{fs} is 0.47(13) in the continuum limit, which agrees well with the experimental value of 0.478(5). A comparison with a NRQCD calculation [35] is given in Figure 2. Our result is also consistent with CP-PACS result from anisotropic lattices with anisotropy $\xi = 3$ [34]. For a detailed discussion on the hyperfine splitting, we refer the reader to Ref. [18].

C. Excited states

We first discuss our result for exotic hybrid states, in particular the 1^{-+} meson. Figure 3 is an effective mass plot of the exotic hybrid meson 1^{-+} , with each data set corresponding to a particular fuzzing parameter α as defined in Eq. 3.5. With a very fine temporal resolution,

we are able to obtain many measurements at short time separations to facilitate multi-state fits and extract both the ground state and excited state masses more precisely. By employing different quark smearing and gauge link fuzzing parameters, we obtain different coupling to the ground and excited states (referred to as different “channels” later). With multiple channels, the multi-state fits are quite stable. We fit the data to 2-state and in some cases 3-state ansatz to obtain the ground state mass. Figure 4 shows the multi-state fits for meson 1^{-+} , the ground state mass obtained from 1-state fit at large time separation ($t > 7$) is consistent with the results from a 2-state fit ($t > 4$) and a 3-state fit ($t > 1$), which rules out contamination of the ground state by excited states and clearly demonstrates the advantage of anisotropic lattices. For the hybrid states, we did not observe as strong a dependence on the quark field smearing as seen for the conventional $\bar{q}q$ mesons, which indicates that the excitation is likely to originate from the excitation of gluonic constituents. For a self-consistency check, we measured the 1^{-+} exotic meson with 3 different operators ($a'_0 \times \nabla$, $b_1 \times \nabla T_1$, and $\rho \times B T_1$) and obtained consistent values. Fig. 5 shows the continuum extrapolation ($\mathcal{O}(a^2)$) using three different operators, with the continuum value being 4.428(41) GeV, 4.409(75) GeV and 4.41(18) GeV for $\rho \times B T_1$, $a'_0 \times \nabla$, and $b_1 \times \nabla T_1$ irrespectively. The operator $\rho \times B T_1$ has the best signal and smallest statistical error, so we quote the final result 4.428(41) GeV for the 1^{-+} mass from this operator.

Various models of QCD, such as the bag models [22,23], the flux-tube model [24], and the QCD sum rules [25,26] have been used to study these hybrid states. For the charmonium hybrid meson, the adiabatic bag model predicts a $1^{-+} c\bar{c}g$ state of 3.9 GeV [23] and the QCD sum rules predicts 4.1 GeV [26]. We show the comparison of our 1^{-+} result to previous lattice results [1] in Fig. 7. The result from isotropic lattices (MILC [28]) has large systematic uncertainties due to a possible contamination from excited states. Previous results from NRQCD calculations [27,36] are quite close to ours, which can be explained by the expectation that the quarks in a hybrid meson move more slowly than those in the lowest lying $c\bar{c}$ states (as indicated by the hybrid potential study [37]), thus making the relativistic corrections small. However, the NRQCD calculations are done on rather coarse lattices and the masses can not be extrapolated to the continuum limit to control the lattice discretization errors.

In addition to the exotic 1^{-+} meson, we also measured two other exotic hybrid mesons: 0^{+-} and 2^{+-} . They are heavier than the 1^{-+} meson, with masses of 4.70(17) GeV and 4.895(88) GeV, respectively. No clear signal is obtained for 0^{--} , which is predicted by phenomenological models to be even more massive than the 2^{+-} state. The QCD Sum rules gives an estimate of 5.9 GeV [38] for the 0^{--} state, around 1 GeV above the 2^{+-} state. Clearly it is challenging to extract such a huge excitation from the noise. Higher anisotropies may help, but a more efficient operator than our $a_1 \times \nabla A_1$ is probably also necessary.

Most of our meson operators which can potentially couple to non-exotic hybrid states actually mix strongly with the conventional $q\bar{q}$ mesons with the same quantum number J^{PC} , as indicated by the degenerate masses from different operators shown in Table II. For example, operator $\pi \times B T_1$ has an explicit chromo-magnetic field, making it a potential operator for the hybrid meson 1^{--} . However, our calculation shows that it has the same mass as the conventional 1^{--} (see Table II). The only exception we find is the 2^{-+} signal from $\rho \times B T_2$, which is a very good candidate for a non-exotic hybrid meson. First, its dependence on quark field smearing and gauge link fuzzing is identical to the exotic hybrid

mesons 1^{-+} from $\rho \times B_1 T_1$. Second, its mass is much larger than the conventional $\bar{q}q$ meson. However, further mixing test must be done to rule out the possibility that it is the radial excitation of $L = 2$ conventional 2^{-+} .

A selection rule analysis [39,40] shows that the width of a charmonium hybrid meson is narrow if it lies below the $D^{**}D$ threshold (4.287 GeV). Our result for the exotic hybrid 1^{-+} is 4.365(47) GeV, slightly above the $D^{**}D$ threshold, so the hybrid meson is expected to be broad. However, the conclusion is not final due to the ambiguity of scale setting procedure for quenched calculations.

As a new result from lattice QCD, we also obtain reliable predictions for higher, orbitally excited mesons with $L = 2$ and 3 (D-wave and F-wave), which provide more information about the long range interaction than S-wave or P-wave mesons. The D-wave mesons ($J^{PC} = 2^{-+}, 2^{--}, 3^{--}$) are around 3.9 GeV, above the $D\bar{D}$ threshold (3.7 GeV), and F-wave mesons ($J^{PC} = 3^{++}, 3^{+-}$) lie at 4.15 GeV, above the $D\bar{D}$ threshold, but still below the $D^{**}D$ threshold.

D. Systematic errors

The excited states have larger spacial extent than the lowest lying states, so the results for excited states are more likely to suffer from finite volume effects than the lowest lying states. Therefore, we compare the masses of all excited states obtained from two different lattice sizes ($N_s = 8$ and $N_s = 16$ at $\beta = 5.7, \xi = 2$) and find almost no finite size effect, as shown in table IV. This is consistent with previous NRQCD study [36,41], which found no finite volume effect for a spacial extent larger than 1.2 fm. So we conclude that there is no discernible finite volume effect on our excited state masses.

The second source of error is the imperfect tuning of the bare velocity of light ν_t , which is found to have a rather big effect on the fine structure [18]. Using a $\beta = 5.7, \xi = 4, 8^3 \times 64$ lattice, we vary ν_t by about 10%, which corresponds to about 5% change in the renormalized velocity of light. The results are given in table V, the changes in excited masses are all less than 2% and negligible within errors.

The quenched approximation is the largest source of systematic error. The running of the coupling constant is not correct without the dynamic light quarks. The ratio $R_{2S} = (2S - 1S)/(^1P_1 - 1S)$ from our quenched lattices is 1.55(9), which is 15% higher than the experimental value of 1.34. It affects our result in two ways. First, we convert our lattice results to physical units with lattice scales set by the $^1P_1 - 1S$ splitting, which is ambiguous due to quenched approximation. Second, we tune our quark mass to the charmed quark mass by matching the $1S$ mass to its experimental value of 3.067 GeV using this $^1P_1 - 1S$ scale, which in turn may affect our final results. For our excited spectrum, the later can be neglected because the mass splitting between a excited state and lowest S-wave meson mass $1S$ is insensitive to quark mass. To demonstrate this mass insensitiveness, we measure the excited states on a $\beta = 5.7, \xi = 4$ lattice with two different quark masses $m = 0.32$ and $m = 0.25$ (corresponding to $1S$ mass of 3.383 GeV and 3.029 GeV) and find no mass dependence (as shown in table V. However, for the spin splitting which is approximately inversely proportional to the quark mass, the effect is large (eg. a 5% correction (increase) in scale will cause a 5% increase in the $1S$ mass, which makes the spin splitting in lattice

units 5% smaller than what it should be, so the final result for the spin splitting is 10% larger).

VI. CONCLUSION

We have accurately determined the masses of many new and yet unobserved charmonium states (both conventional $c\bar{c}$ mesons and hybrid $c\bar{c}g$ mesons) from first principles using a fully relativistic anisotropic lattice QCD action. While all the new states are predicted above the $D\bar{D}$ threshold, we believe that the exotic hybrids may still be sufficiently long-lived to warrant an experimental search in the energy region near and above the $D^{**}D$ threshold of 4.287 GeV. This will be an important effort to validate non-perturbative QCD at low energies. We add further evidence that a fully relativistic treatment of the heavy quark system is well suited to control the large systematic errors of NRQCD. In addition, the anisotropic lattice formulation is a very efficient framework for calculations requiring high temporal resolutions, which is crucial for the study of high excitations. The quenched approximation, which is the major remaining systematic error in our calculation, will be addressed by future full QCD calculation. Full QCD anisotropic lattice action has been implemented for staggered fermion and used for thermodynamics study [42]. In addition to the heavy-heavy system, an anisotropic lattice is also a natural framework to study heavy-light systems.

ACKNOWLEDGMENTS

We would like to thank Prof. Norman Christ for his constant support and many valuable suggestions. We are grateful for many stimulating discussions with Prof. Robert Mawhinney. This work is supported by the U.S. Department of Energy. Numerical simulations were conducted on the QCDSP super computers at Columbia University and Brookhaven RIKEN-BNL Research Center.

APPENDIX A: CONVENTIONS

In this section, we describe the conventions used in this paper. The variable x specifies the coordinates in the 4-dimensional (space-time) volume, with extent N_s along the spacial directions and N_t along the time direction. The spacial physical lattice size are given by $L_s = N_s * a_s$. $\mathbf{x}$ is the 3-dimensional spacial coordinate, and t is the time coordinate. $\Psi(x)$ or $q(x)$ represents a fermion field.

The definitions of s_{ijk} and $S_{\alpha jk}$ ($\alpha=1,2$) are:

$$s_{ijk} = |\epsilon_{ijk}| \quad (\text{A1})$$

$$S_{\alpha jk} = 0(j \neq k), S_{111} = 1, S_{122} = -1, S_{222} = 1, S_{233} = -1 \quad (\text{A2})$$

APPENDIX B: MESON CORRELATOR AND MESON OPERATORS

1. Meson correlator calculation

We describe how to construct meson correlators from quark propagators. For simplicity, we discuss the correlation function between sink meson operator $\mathcal{M}(t) = \bar{\Psi}_2(\mathbf{x}_2, t) \vec{O}_i \Gamma_\alpha \Psi_1(\mathbf{x}_1, t)$, and source operator $M(t_0) = \bar{\Psi}_2(\mathbf{y}_2, t_0) \vec{O}_j \Gamma_\beta \Psi_1(\mathbf{y}_1, t_0)$, in which Γ_α and Γ_β are a combination of Dirac γ -matrices, and $\vec{O}_i$ and $\vec{O}_j$ are lattice derivative operators. More generally, the source operator can be any operator (or a combination of different meson operators) that creates the state of interest.

The correlator is calculated as follows:

$$\begin{aligned}
\langle \mathcal{M}^\dagger(t) M(t_0) \rangle &= \langle \Psi_1^\dagger(\mathbf{x}_1, t) \Gamma_\alpha^\dagger \vec{O}_i^\dagger \gamma_4 \Psi_2(\mathbf{x}_2, t) \bar{\Psi}_2(\mathbf{y}_2, t_0) \vec{O}_j \Gamma_\beta \Psi_1(\mathbf{y}_1, t_0) \rangle \\
&= \langle \bar{\Psi}_1(\mathbf{x}_1, t) \gamma_4 \Gamma_\alpha^\dagger \gamma_4 \vec{O}_i^\dagger \Psi_2(\mathbf{x}_2, t) \bar{\Psi}_2(\mathbf{y}_2, t_0) \vec{O}_j \Gamma_\beta \Psi_1(\mathbf{y}_1, t_0) \rangle \\
&= \langle \gamma_4 \Gamma_\alpha^\dagger \gamma_4 G_2(\mathbf{x}_2, t; \mathbf{y}_2, t_0) \Gamma_\beta G(\mathbf{y}_1, t_0; \mathbf{x}_1, t) \vec{O}_i^\dagger \rangle \\
&= \langle \gamma_5 \gamma_4 \Gamma_\alpha^\dagger \gamma_4 G_2(\mathbf{x}_2, t; \mathbf{y}_2, t_0) \Gamma_\beta \gamma_5 [\vec{O}_i G(\mathbf{x}_1, t; \mathbf{y}_1, t_0)]^\dagger \rangle \\
&= \langle \Gamma'_\alpha G_2(\mathbf{x}_2, t; \mathbf{y}_2, t_0) \Gamma'_\beta [\vec{O}_i G(\mathbf{x}_1, t; \mathbf{y}_1, t_0)]^\dagger \rangle \quad (\text{B1})
\end{aligned}$$

Here, we first set up the source (box or smeared) and apply the derivative operator $\vec{O}_j$, then we calculate the quark propagator $G(\mathbf{y}_1, t_0; \mathbf{x}_1, t) = \langle \bar{\Psi}_1(\mathbf{x}_1, t) \vec{O}_j \Psi_1(\mathbf{y}_1, t_0) \rangle$. Utilizing

$G(\mathbf{y}_1, t_0; \mathbf{x}_1, t) = \gamma_5 G^\dagger(\mathbf{x}_1, t; \mathbf{y}_1, t_0) \gamma_5$, we arrive at equation B1. Then we apply the sink derivative operator $\vec{O}_i$, insert gamma matrices $\Gamma'_\alpha = \gamma_5 \gamma_4 \Gamma_\alpha^\dagger \gamma_4$ and $\Gamma'_\beta = \Gamma_\beta \gamma_5$, and do color and Dirac indices contraction. We need two quark propagators: $G(\mathbf{x}_1, t; \mathbf{y}_1, t_0)$ and $G_2(\mathbf{x}_2, t; \mathbf{y}_2, t_0)$. In practice, we can reuse the same quark propagators for multiple meson operators.

2. Meson operators and naming convention

Meson operators with no derivative operators are named $a_0, a'_0, \pi, \rho, a_1$, and b_1 , as listed in the second row of table VI. A meson operator with a lattice derivative operator is named $X \times Y_R$, where X represents the gamma matrix, Y is the derivative operator (∇, D or B), and R indicates the O_h irreducible representation of the meson operator (R is usually omitted if it is unique).

APPENDIX C: HYPER-CUBIC GROUP

The five irreducible representations of hyper-cubic group O_h and our choice of basis vectors for these representations are:

$$\begin{aligned}
A_1 : \quad \psi^1 &= (x^2 + y^2 + z^2) \\
A_2 : \quad \psi^2 &= xyz \\
E : \quad (\psi_1^3, \psi_2^3) &= (x^2 - y^2, y^2 - z^2) \\
T_1 : \quad (\psi_x^4, \psi_y^4, \psi_z^4) &= (x, y, z) \\
T_2 : \quad (\psi_{yz}^5, \psi_{xz}^5, \psi_{xy}^5) &= (yz + zy, zx + xz, xy + yx)
\end{aligned} \tag{C1}$$

The decomposition of often used direct products of hyper-cubic group irreducible representations:

$$\begin{aligned}
T_1 \otimes T_1 &= A_1 \oplus T_1 \oplus T_2 \oplus E \\
T_1 \otimes T_2 &= A_2 \oplus T_1 \oplus T_2 \oplus E
\end{aligned} \tag{C2}$$

Clebsch-Gordon coefficients are defined as:

$$\psi(J, M) = \sum_{m_1, m_2} C(J, M | J_1, m_1; J_2, m_2) u(J_1, m_1) v(J_2, m_2) \tag{C3}$$

Table VIII, IX, are Clebsch-Gordon coefficients used to construct the meson operators in table VII

TABLE II. Charomonium spectrum results expressed in GeV. The meson operators are sorted by the continuum quantum number (J^{PC}) of the ground state. Only the ground state masses are listed in this table. The lattice scale is set by the $^1P_1 - 1S$ splitting. Continuum results from $\mathcal{O}(a_s^2)$ and $\mathcal{O}(a_s)$ extrapolations are listed in the last two columns. The continuum extrapolation procedure is described in section V A. The errors quoted here do not include the uncertainties in the physical scale.

TABLE IX. Clebsch-Gordon coefficients of $T_1 \otimes T_2 = A_2 \oplus E \oplus T_1 \oplus T_2$

FIG. 1. Quenched charmonium spectrum. The experimental values are shown as short horizontal lines. The long horizontal dashed lines mark the $D\bar{D}$ and $D^{**}D$ thresholds. The mesons (please refer to appendix B2 for our naming convention) plotted are: $\pi(0^{-+})$, $\rho(1^{-+})$, $b_1(1^{+-})$, $\rho \times \nabla A_1(0^{++})$, $\rho \times \nabla T_1(1^{++})$, $\rho \times \nabla T_2(2^{++})$, $\pi \times D T_2(2^{-+})$, $\rho \times D T_2(2^{-+})$, $\rho \times D A_2(3^{-+})$, $a_1 \times D A_2(3^{++})$, $b_1 \times D A_2(3^{+-})$, $a_1 \times B A_1(0^{+-})$, $\rho \times B T_1(1^{+-})$, and $a_1 \times B T_2(2^{+-})$. Some of the low-lying meson ($\pi(0^{-+})$, $\rho(1^{-+})$, $b_1(1^{+-})$) are taken from Columbia group's previous work [18]. The lattice scale is set by the $^1P_1 - 1S$ splitting. The numerical values are listed in table II.

FIG. 2. P-wave triplet splitting ratio $R_{fs} = ({}^3P_2 - {}^3P_1)/({}^3P_1 - {}^3P_0)$. Comparison is shown with NRQCD results with relativistic corrections up to $O(mv^4)$ and $O(mv^6)$ [35].

FIG. 3. Effective mass of the 1^{-+} exotic meson for $\beta = 6.1$ and $\xi = 2$ with different APE-style fuzzing coefficients α as defined in equation 3.5.

FIG. 4. Masses from multi-exponential fits of $\rho \times B_{T_1}$ propagator (the ground state is the exotic 1^{-+}) for $\beta = 6.1$ and $\xi = 2$. The upper band of solid circles and two added upper bands of solid triangles show the effective excited state masses.

FIG. 5. Continuum extrapolation (as outlined in section V A) of the exotic hybrid 1^{-+} (mass above $1S$) with different meson operators ($\rho \times B_{T_1}$, $a_0' \times V$, and $b_1 \times V_{T_1}$).

FIG. 6. Continuum extrapolation of the exotic hybrid 0^{+-} ($a_1 \times B_{A_1}$) and 2^{+-} ($a_1 \times B_{T_2}$).

FIG. 7. Comparison of charmonium hybrid meson 1^{-+} mass (relative to the spin-averaged S-wave meson mass $1S$) as determined by this work, NRQCD (CP-PACS [36]), and isotropic relativistic lattice QCD (MILC collaboration [28]).
